Huge seeds (be they insects, bumble-bees, or corn or sunflower or others) need pollination to produce fruit or flowers. The insects or other large pollinators are often forced by conditions beyond their control (such as a lack of food or a lack of warmth) to produce offspring sooner than they would otherwise. This is referred to as premature dispersion of the offspring, which causes a sub-population to have an increased proportion of the genetic material of the parent population. This is generally regarded as a negative event, as the individuals with the premature offspring are not fit to survive, and the population as a whole is smaller. This premature dispersion of the offspring is also usually correlated with an overall decrease in the population size. However, there are other reasons for this premature dispersion, and occasionally the offspring may be larger and more fit than those that did not leave the parent population. Bee pollen, for example, is a food source for honey bees. Pollen is a food source of larger pollen-eating insects, birds and bats. Bees can have a large effect on the pollination of plants, as they can travel great distances to reach their preferred flowers. If most of the insects with which they have a preference for pollination are not present, the plants may produce little or no fruit or flower. Also, if the bees are not well-fed, they are less able to perform their pollination duties, and the plants produce fewer fruits or seeds. There are a number of explanations for why bees are in decline, but the main one is that pollination is required in order for plants to produce fruit, which in turn provides nutrients to animals and humans. As animal and human food is increasingly restricted and pollination is increasingly important, the problems for bees are likely to get much worse. Therefore, attempts have been made to restore the bee population by creating artificial habitats for the bees. This is achieved by providing them with suitable pollen, nectar and water sources,
